Abstract

In fragile states like the Central African Republic, conflict and institutional fragility severely constrain traditional data collection, impeding the design of targeted interventions. This paper develops a geospatial dashboard harnessing alternative data—nighttime lights, satellite imagery, geocoded infrastructure inventories, and conflict records—to construct high-resolution vulnerability indices at 5×5-kilometer scale. A Bayesian state-space model disaggregates sectoral GDP, while friction-based metrics measure service accessibility. Cross-validation against the 2021 Harmonized Household Living Conditions Survey confirms strong predictive validity: economic capacity and service access indices correlate positively with household wealth, while lethal conflict exposure paradoxically targets wealthier areas, consistent with rent-seeking dynamics.

*Corresponding author. This work is part of the Central African Republic Public Finance Review Report: Enhancing the Transparency, Sustainability, and Effectiveness of the Public Sector, produced under the EAWM2 Unit (P500483, TTL: Pierre Jean-Claude Mandon; Co-TTLs: Diderot Guy D’Estaing Sandjong Tomi and Blaise Ehowe Nguem). The authors are grateful to Ana Maria Oviedo (Lead Economist), Gervais Yama (Senior Statistician), and Davy Mokosso (Consultant) for their invaluable support in securing the EHCVM household survey and geolocation data on key national infrastructure. They also extend their thanks to colleagues at the World Bank for their insightful feedback.

Access to reliable and timely granular data is critical for effective policy making, yet remains extremely challenging in low-income countries (LICs) like the Central African Republic (CAR). This data scarcity stems from prohibitive survey costs, institutional capacity constraints, security challenges in conflict-affected regions, and insufficient technical infrastructure [Jean et al., 2016, Blumenstock, 2018]. Recent innovations offer promising pathways to overcome these limitations. Satellite imagery has enabled poverty mapping at unprecedented spatial resolution [Jean et al., 2016], call detail records from mobile phones have facilitated measurement of population mobility and economic shocks [Blumenstock et al., 2015, Steele et al., 2017], remotely sensed vegetation indices have been used to monitor agricultural productivity [Burke and Lobell, 2017], and mobile money transactions have provided real-time insights into economic activity when traditional data collection was impossible [Asenso-Okyere and Mekonnen, 2012]. Nevertheless, these methodologies face challenges including algorithmic bias, representativeness concerns, and privacy considerations that necessitate careful validation against ground-truth data [Wesolowski et al., 2012, Blumenstock, 2018].

In CAR’s context, where the last comprehensive census was conducted in 2003¹ and where conflict has severely disrupted statistical capacity, these alternative data approaches have particular relevance. Recent empirical analysis employing the synthetic control method (SCM) yields compelling evidence regarding the disastrous economic consequences of CAR’s ongoing civil war after one decade of conflict [Mandon et al., 2025].² According to the World Bank’s 2023 Poverty Assessment, CAR remains one of the world’s poorest nations, with approximately two-thirds of the population living below the international poverty line of US\$2.15 per day (in 2017 PPP terms). Extreme poverty is particularly concentrated in rural areas, where about 74.2 percent of households fall below the poverty threshold, compared to 61.1 percent in urban centers and 40.1 percent in Bangui, the nation’s capital [World Bank, 2023]. As of end August 2025, approximately 1.1 million Central Africans remain at risk of statelessness (e.g., lack of birth registration, or the inability to prove links to any state), including around 442,000 internally displaced persons (IDPs) and 669,000 refugees in neighboring countries, severely compromising household resilience and exacerbating vulnerability to shocks.³

CAR’s government still has limited control outside major towns.⁴ This limited state authority renders traditional survey-based data collection not only logistically challenging but often physically dangerous. A dashboard integrating remote sensing and geocoded data is invaluable in this context. Satellite-derived indicators offer near real-time monitoring of population movements and economic capacities in remote areas [Jean et al., 2016]. Since 2022, ICASEES has collected extensive cartographic data on critical infrastructure—schools, health facilities, water points—providing an unprecedented baseline for service delivery planning [World Bank, 2023]. Fathom’s high-resolution flood risk mapping offers critical insights for disaster preparedness,⁵ while geocoded conflict event data from ACLED [Raleigh et al., 2010], combined with the friction surface model of Kosmidou-Bradley et al. [2025], can inform violence hazards. Such a dashboard would enhance the government’s capacity to implement spatially targeted recovery and peacebuilding interventions [World Bank, 2022].

This paper addresses two central objectives. First, it develops a spatially disaggregated composite index that integrates multiple dimensions of vulnerability at a granular level, operationalized through a geospatial analytics dashboard. This approach is particularly valuable where subnational statistics are limited and socio-economic surveys outside the capital are sparse.⁶ The framework simultaneously assesses four domains:

- i) The analysis quantifies sectoral local economic capacities through a state-space model improved

¹For further information, see the official documentation from the *Institut Centrafricain des Statistiques des Etudes Economiques et Sociales* (ICASEES) available [here](#).

²The hostilities that commenced in December 2012 have imposed substantial economic costs, with estimates indicating that the conflict precipitated a decline in GDP per capita ranging from 45.3 to 47.8 percent over the 2013-2022 period. This significant contraction translates to an aggregate GDP shortfall of US\$29.7 billion to US\$32.4 billion in purchasing power parity (PPP) terms.

³Additionally, as of end September 2025 CAR hosted around 63,000 international refugees and asylum seekers, mostly from neighboring Sudan, putting additional pressure especially on the northeastern Vakaga prefecture. For further information, see the online data from the Office of the United Nations High Commissioner for Refugees (UNHCR), available [here](#) and [here](#).

⁴For further information, see the online 2025 keynote from Human Right Watch, available [here](#).

⁵Fathom data is free of charge for CAR and 15 other climate vulnerable countries. For further information, see the official Fathom website, available [here](#).

⁶For instance, the 2011 and 2023 World Bank Enterprise Surveys (WBES), including the related Informal Sector Enterprise Survey (ISES) and Survey of Micro Firms (ESM), cover exclusively Bangui and Berbérati (i.e., the third-largest city after Bimbo). For further information, see the WBES data catalog, available [here](#).

from [Henderson et al. \[2012\]](#) to account for propagation of uncertainty, and the integration of relevant daytime satellite imagery with precisely geocoded private business locations, enabling the identification of both primary and secondary & tertiary economic clusters.

- ii) It measures physical accessibility to essential public services by constructing infrastructure indices that incorporate both the spatial distribution of service delivery points and quality-adjusted capacity metrics (e.g., operational status). This approach accounts for the friction surface model mentioned earlier.
- iii) It incorporates physical exposure to flood hazards, a dimension of particular relevance given the concentration of population settlements along riverine corridors, most notably in Bangui.
- iv) It evaluates physical exposure to lethal conflict risk through spatiotemporal analysis of historical event patterns and the implementation of the friction surface model.

Second, the paper leverages the 2021 Harmonized Household Living Conditions Survey (*Enquête Harmonisée sur les Conditions de Vie des Ménages*, EHCVM)—the only comprehensive socio-economic household survey implemented since the onset of civil war in December 2012—to analyze welfare dynamics across heterogeneous population segments, including IDPs. This allows us to cross-check the reliability of the proposed dashboard against one of the few nationally representative and relevant surveys available.⁷

This paper yields three principal empirical findings. First, the multidimensional vulnerability assessment reveals pronounced spatial inequalities across CAR, with economic activity largely concentrated in Bangui while vast rural areas exhibit minimal economic presence and severely constrained access to essential services. Cross-validation using the 2021 EHCVM demonstrates strong predictive validity for our satellite-derived indices, with GDP and all service access measures exhibiting consistently positive and statistically significant associations with household wealth. Notably, the health access index achieves its strongest significance under the most demanding specification with prefectural fixed effects, suggesting that proximity to health facilities captures meaningful within-prefecture variation in welfare. Primary-sector GDP remains positively associated with household wealth, while secondary and tertiary sectors lose significance once fixed effects are included, likely reflecting their concentration in a few urban areas, primarily Bangui.

Second, the analysis uncovers a counterintuitive positive correlation between lethal conflict exposure and household wealth, reflecting strategic targeting by armed groups of economically valuable areas rather than protective effects of prosperity. These findings underscore the complex relationship between development and security in fragile states, where relative prosperity may paradoxically increase rather than decrease exposure to violence. Regarding flooding, the data indicate that flood exposure correlates with wealth primarily through administrative-level factors (e.g., Bangui’s effect) rather than localized, fine-grained variations.

Third, the methodological framework successfully bridges the gap between alternative data sources and ground-truth welfare outcomes, providing a scalable template for monitoring multidimensional vulnerability in data-scarce environments. The 5×5 kilometer resolution enables identification of potential deprivation hotspots that would be obscured by traditional administrative-unit analyses, while the standardized grid system ensures replicability across diverse analytical contexts.

The remainder of this paper proceeds as follows. Section II establishes the empirical context of CAR’s extreme fragility and data constraints. Section III details the methodological approach, including the Bayesian state-space model for GDP disaggregation and the construction of infrastructure accessibility and risk exposure indices. Section IV presents the spatial vulnerability dashboard and validates the indices against household survey data. Section V discusses policy implications and broader applicability.

⁷Conducted in 2021 by ICASEES, the survey aimed to reach 6,000 households nationally and an additional 600 households in IDP sites. The national statistical institute received official support from the Ministry of Economics, Planning, and International Cooperation (MEPIC), along with technical and financial support from the Joint Data Center on Forced Displacement, UNHCR, and the World Bank. For further information, refer to the World Bank’s Poverty Assessment [[World Bank, 2023](#)].

I Context

CAR exemplifies the interplay between extreme deprivation and the urgent need for innovative data solutions in fragile settings. Decades of political instability since independence in 1960 have entrenched CAR as one of the world’s poorest nations [World Bank, 2022]. The economy, heavily reliant on rain-fed subsistence agriculture, local agro-processing, and retail trade in imported products, suffers from severely limited diversification. With an official export basket overwhelmingly composed of diamonds, gold, logs, and sawnwood, resource wealth is often channeled into embezzlement and ad-hoc arrangements with external actors rather than development. Weak administration further impedes provision of essential services, leaving rural populations particularly isolated. According to the World Bank’s Poverty Assessment [World Bank, 2023], approximately two-thirds of CAR’s population survives below the international poverty line of US\$2.15 per day, with rural poverty rates reaching 74.2 percent compared to 40.1 percent in Bangui. This multidimensional vulnerability, compounded by recurrent armed violence and climate hazards, positions CAR as a critical case for studying poverty dynamics where traditional data systems falter.

Data scarcity in CAR poses a formidable barrier to understanding and addressing this vulnerability. Persistent insecurity and logistical constraints render conventional household surveys sporadic, with the last comprehensive census dating to 2003. This absence of granular, timely data obscures subnational disparities, particularly in conflict-ridden and remote regions where poverty is most severe. Traditional statistical methods, hampered by limited state authority beyond urban centers, fail to capture the spatial and temporal heterogeneity of socio-economic conditions. The 2021 EHCVM stands as a rare exception, yet its scope remains insufficient for ongoing monitoring or localized policy design, without complementary updated information. Consequently, alternative data sources—satellite imagery, and geospatial analytics—emerge as vital tools to bridge these gaps, offering high-resolution insights into economic capacity, service access, and vulnerability to shocks.

CAR’s extreme conditions not only necessitate these data innovations but also provide a unique testing ground for refining them. Combining economic capacity, service access, and exposure to hazards into a multidimensional framework operationalized through geospatial dashboards can empower policy makers to prioritize recovery efforts where state authority is weakest, aligning with donor-supported peacebuilding initiatives. By dissecting the interplay of conflict, governance failures, and economic stagnation, research in CAR yields insights that extend beyond its borders, informing strategies for poverty alleviation in other low-capacity states.

II Data and methodology

A Estimating local economic capacities

1 State-space model

This study employs a state-space framework to link national GDP with its sectoral components since 1960. National GDP in logarithmic scale is denoted y_t , while $y_{1,t}$, $y_{2,t}$, and $y_{3,t}$ represent the primary, secondary, and tertiary sectors. The true (latent) value of each component is $y_{s,t}^*$ for $s \in \{1, 2, 3\}$.

Observed quantities are related to latent sectoral GDPs through:

$$y_t = \sum_{s=1}^4 \pi_s y_{s,t}^* + \nu_t, \quad (1)$$

$$y_{s,t} = y_{s,t}^* + \omega_{s,t}, \quad s = 1, \dots, 3, \quad (2)$$

$$\ell_t = \alpha \sum_{s=1}^3 y_{s,t}^* + v_t, \quad (3)$$

where π_s are unknown sectoral weights in national GDP, and α captures the elasticity between NTLs and economic activity [Henderson et al., 2012, Guerrero and Mendoza, 2019]. Errors $\nu_t, \omega_{s,t}, v_t$ are independent Gaussian variables with unknown variances. Sectoral GDPs evolve as random walks:

$$y_{s,t}^* = y_{s,t-1}^* + \varepsilon_{s,t}, \quad s = 1, \dots, 3. \quad (4)$$

Estimation and predictions

Estimation is fully Bayesian, combining expert knowledge with uncertainty propagation. Sectoral weights follow a Dirichlet prior:

$$\pi \sim \mathcal{D}(54.5, 18.2, 27.3),$$

encoding prior beliefs that, structurally, GDP derives mainly from the primary sector (54.5 percent), followed by the secondary (18.2 percent), and tertiary (27.3 percent). The elasticity α has a Gaussian prior centered at zero with precision 10, and all variance parameters receive weakly informative inverse-Gamma priors $\mathcal{IG}(0.001, 0.001)$. Posterior inference is implemented in **Rjags** [Plummer, 2023], using four chains of 50,000 iterations (5,000 burn-in, thinning factor 5). Convergence diagnostics (Gelman–Rubin statistics) are below 1.01 for all key parameters.

Predictions are drawn from the posterior predictive distribution, which integrates uncertainty from states, process noise, observation noise, and parameters. For horizon h , the predictive variance of national GDP can be decomposed as:

$$\begin{aligned} \text{Var}(y_{T+h} \mid \mathcal{D}) = & \underbrace{\pi^\top P_T \pi}_{\text{uncertainty on latent states}} \\ & + \underbrace{h \pi^\top Q \pi}_{\text{accumulated process noise}} \\ & + \underbrace{\sigma_\nu^2}_{\text{observation noise}} \\ & + \underbrace{\text{Var}_{\pi, Q, \sigma_\nu^2}[\cdot]}_{\text{parameter uncertainty}} \end{aligned} \tag{5}$$

where P_T is the posterior covariance of latent sectoral GDP at time T , and Q the variance of sectoral shocks. This decomposition highlights that credible intervals widen with the forecast horizon not only because of state and observation errors, but also due to the accumulation of process uncertainty and the propagation of parameter uncertainty.

Estimation

Posterior estimation of sector contributions to national GDP equals 44.3, 23.1, and 32.6 percent for the primary, secondary, and tertiary sectors, respectively (see Figure 1). The secondary sector, with a contribution of about 23 percent—less than the tertiary sector—might appear elevated for a sub-Saharan African country, but it is mostly driven by limited processing of raw materials, especially agricultural products.⁸

Figure 1: Posterior samples of sectoral GDP weights (π_1, π_2, π_3).

Source: Authors' construction. *Notes:* Scatterplots above the diagonal show pairwise relationships between the primary, secondary, and tertiary sector weights. Below the diagonal, joint densities highlight correlations, while the diagonal displays marginal posterior densities for each parameter. These samples are drawn from the Bayesian posterior distribution, incorporating state, process, observation, and parameter uncertainties.

Predictions

Two prediction strategies are implemented to assess model performance. The first approach employs *smoothed estimates*, which incorporate all available observations (1961–2022) to produce posterior state estimates at each time point. This yields the most accurate retrospective assessment of sectoral GDP dynamics, as the Kalman smoother integrates information from both past and future observations relative to any given time t . Credible intervals in this case reflect primarily parameter uncertainty and measurement error, as state uncertainty is minimized through the use of the complete data series.

The second approach implements *out-of-sample forecasting* to evaluate predictive validity. The model is estimated using only data from 1961–2019, and forecasts are generated for the holdout period 2020–2022. This recursive forecasting exercise starts from the last observed state in 2019 and propagates forward without incorporating subsequent observations, thereby accumulating both process noise and state uncertainty over the forecast horizon. As expected, credible intervals widen substantially in the out-of-sample predictions (Figure 2, panels e–h) compared to smoothed estimates (panels a–d), reflecting the compounding effects of parameter uncertainty, process variability, and the absence of data-based state corrections. This validation exercise demonstrates the model's ability to generate plausible short-term forecasts while acknowledging increased uncertainty for unobserved periods.

⁸According to ICASEES, the secondary sector in CAR is largely driven by local agro-processing (e.g., breweries, beverage and food processing, cigarettes, soap production). Official national accounts data are available [here](#).

Figure 2: State-space model predictions. Panels (a)–(d): smoothed estimates using all observations (1961–2022). Panels (e)–(h): out-of-sample forecasts (trained on 1961–2019, forecasted 2020–2022).

Source: Authors' construction. *Notes:* Shaded areas represent 80% credible intervals from MCMC posterior samples. Black lines: observed values. Vertical dashed line in bottom row indicates train/test split.

2 GDP spatial allocation methodology

The predicted median sectoral GDP values y_{st}^* obtained from the state-space model are spatially allocated for each year using remote sensing indicators. This analysis distinguishes between the primary sector and the combined secondary and tertiary sectors based on relevant remote sensing and geocoded data sources detailed in Section A.1 of the Appendix.

For the primary sector, the local GDP at location i and time t is calculated as:

$$\begin{aligned} y_{Prim.i,t}^* = y_{Prim.t}^* \cdot & \left(\text{shareForest}_{i,t} \cdot \frac{0.05}{2} \right. \\ & + \text{shareDeforestation}_{i,t} \cdot \frac{0.05}{2} \\ & + \text{shareCropland}_{i,t} \cdot \frac{0.625}{3} \\ & + \text{shareNDVI}_{i,t} \cdot \frac{0.625}{3} \\ & + \text{sharePopulation}_{i,t} \cdot \frac{0.625}{3} \\ & + \text{shareWater}_{i,t} \cdot 0.05 \\ & \left. + \text{shareGrassland}_{i,t} \cdot 0.275 \right). \end{aligned} \quad (6)$$

This allocation scheme reflects the sectoral composition of primary activities based on historical data from ICASEES, where forestry accounts for around 5 percent of primary sector activity, agriculture represents 62.5 percent, pastoral activities constitute 27.5 percent, and water-related activities (e.g., fisheries) comprise the remaining 5 percent.⁹

For the combined secondary and tertiary sectors, the local GDP at location i and time t is calculated as:

$$\begin{aligned} y_{Sec.Ter.i,t}^* = y_{Sec.Ter.t}^* \cdot & \left(\text{shareBuiltup}_{i,t} \cdot \frac{0.975}{3} \right. \\ & + \text{sharePopulation}_{i,t} \cdot \frac{0.975}{3} \\ & + \text{shareSMEs}_i \cdot \frac{0.975}{3} \\ & \left. + \text{shareMines}_i \cdot 0.025 \right). \end{aligned} \quad (7)$$

where $y_{Sec.Ter,it}^*$ represents the sum of the predicted secondary and tertiary sector GDP for a given year. This specification assumes that mining activities account for 2.5 percent of combined secondary and tertiary sector activity, also based on historical data from ICASEES.¹⁰

Total local GDP at time t , denoted $y_{i,t}^*$, is computed as the sum of $y_{Prim.i,t}^*$ and $y_{Sec.Ter.i,t}^*$. All local GDP estimates are normalized using a Min–Max transformation to facilitate comparison with other key components in the geospatial analytics dashboard, including access to key infrastructure and exposure to risks of flooding and lethal conflicts, as detailed below.

The spatial allocation procedure preserves the uncertainty structure implied by the underlying statistical model. All predicted GDPs, y_{st}^* , are first spatially allocated according to Equations (6) and (7), and local uncertainty is then computed as the standard deviation of sectoral GDPs (Figure 3). Most of the uncertainty in our predictions is concentrated in areas where the predicted GDP is relatively higher, namely Bangui and the western regions of the country. The local GDP predictions for the year 2021, obtained from the strategy using past observations, serve as reference values for the vulnerability dashboard and subsequent regression analysis.

⁹Official national accounts data are available [here](#).

¹⁰Ibid. In the ICASEES framework, all extractive activities are classified within the secondary sector.

Figure 3: Local GDP uncertainty

Standard Deviation of GDP, 2021

Source: Authors' construction. *Notes:* The year 2021 is used as the reference year to ensure consistency with the EHCVM survey data. For each cell we compute the Standard Deviation based on the series of all predicted local GDPs in the year 2021.

B Assessing infrastructure access

To complement the local GDP estimates, this analysis incorporates infrastructure access measures into the dataset. The analytical strategy transforms the 100-meter WorldPop “constrained” population raster for CAR [WorldPop, 2020] into a dense lattice of points—one point for every populated cell. This approach treats each person-weighted point as the fundamental unit to which every other layer is linked. To enrich these points, contextual information at the settlement level is added to each point. These contextual variables include population totals, building counts and degree-of-urbanization classes, [Dijkstra et al., 2020] calculated/extracted to GRID3’s settlement polygons [CIESIN and Novel-T, 2021] and are tagged with the administrative codes and populations of the districts in which they fall.¹¹ The result is a single, relational table whose rows behave like households and whose attributes range from fine-scale demographics to aggregate administrative totals.

With this common reference in place, the study assesses physical accessibility to key public goods and services. ICASEES, with the support of the World Bank, provided a nationwide and comprehensive geolocated inventories of essential infrastructure, including all health facilities, primary, secondary, and tertiary schools¹² and water points [World Bank, 2023, 2025]. For each service type, this analysis generates nationwide travel-time surfaces using the Global High-Resolution Updatable Friction Surface (GRUFS), a pair of cost/friction raster datasets that translates on- and off-road movement into minutes of travel [Kosmidou-Bradley et al., 2025]. GRUFS Walking assumes that people are walking, even if on roads, whereas GRUFS Mixed assumes driving speeds on roads, but walking off-road. From these continuous surfaces, the methodology samples, at every population point, the shortest walking time required to reach the nearest facility of each category.¹³ This procedure yields person-specific measures of geographic access that remain consistent across services and can be aggregated up, unweighted or population-weighted, to any spatial unit of interest, including administrative boundaries (e.g. settlement, communes, prefectures). As for the economic capacities, infrastructure access measures for education, health and water access are then normalized with a Min–Max function to allow comparisons across different service types, and geographic areas, as well as other dimensions of the dashboard.

C Evaluating risk exposure to flooding

Flood risk assessment is incorporated using the Fathom Global 3.0 hazard model [Fathom, 2022]. Separate depth grids for fluvial and pluvial flooding were obtained for the baseline year 2020 and for future horizons under various Shared Socioeconomic Pathways (SSP), namely SSP1, SSP2, SSP3 and SSP5 in 2030, 2050 and 2080. For each time slice, this analysis considers return periods from five to 1,000 years, capturing both frequent, low-impact events and rare, catastrophic ones. Maximum water depths from these scenarios were sampled at the same set of population points established in the infrastructure access assessment.

To enable comparison across time horizons and hazard types, this analysis standardizes the depth values. Processing uses Python and ArcPy via ArcGIS Pro version 3.4, with checksums recorded for reproducibility. The flood index employs the SSP2 scenario with the 2030 horizon. Flood risk measures are also normalized using a Min–Max function to facilitate comparison with other dimensions of the dashboard.¹⁴

D Appraising risk exposure to lethal conflicts

Conflict exposure assessment recreates the Spatial Conflict Index Raster (SCIR) with the latest ACLED through December 2024. Following the kernel-density approach laid out by Gevaert and Kosmidou-Bradley [2023], this analysis produces a series of five-year rolling averages (i.e., 2015-20, 2016-21, ...

¹¹For further information, see the documentation, available [here](#).

¹²The inventory encompasses both public and private health facilities and educational establishments. The dataset accounts for the operational status of each facility, distinguishing between active and inactive establishments, and considers exclusively active ones.

¹³The analysis in this study focuses on journeys taken on foot, as other transport modes may not be available to the poorest and most deprived people if private or public transport is unavailable or unaffordable [World Bank, 2023, p.114].

¹⁴Compared to local economic capacities and infrastructure access, higher values indicate greater flood risk exposure, reflecting more detrimental outcomes.

2019-24) alongside a raster summarizing the entire study period. Each surface represents a temporally-smoothed, fatality-weighted intensity score, in terms of standard deviations, that falls off with distance from reported events (i.e., geocoded lethal conflicts).

As with the infrastructure and flood risk assessments, values were extracted directly to the population points, ensuring that every household analogue carries a time-stamped indicator of conflict risk. This approach maintains consistency across all risk measures and enables comprehensive analysis of the relationship between economic capacities and various forms of risk exposure. Conflict exposure measures are also normalized with a Min–Max function to facilitate comparison with other dimensions of the dashboard aforementioned.¹⁵

E Vulnerability Index

Index of Vulnerability (Idx_Vulnerab_Final). This composite index summarizes overall vulnerability for each location (i) averaging six previously defined component indices—each oriented so that larger values mean *worse* conditions—and then (ii) rescaling the result to $[0, 100]$ via Min–Max normalization. The six components are: `Idx_GDP`, `Idx_educ_prim`, `Idx_health`, `Idx_water_access`, `Idx_conflicts`, and `Idx_floods`.

Let i index spatial units and assume each component index $S_{k,i} \in [0, 100]$ (higher = better for GDP and infrastructure components, worse otherwise). First, build an *unnormalized* vulnerability score by reversing the direction of GDP and infrastructure components and taking their mean:

$$V_i = \frac{1}{6} \left[(100 - \text{Idx_GDP}_i) + (100 - \text{Idx_educ_prim}_i) + (100 - \text{Idx_health}_i) + (100 - \text{Idx_water_access}_i) + \text{Idx_conflicts}_i + \text{Idx_floods}_i \right] \quad (8)$$

Min–Max normalization is then applied across all units to obtain the final index, which is multiplied by 100:

$$\text{Idx_Vulnerab_Final}_i = 100 \times \frac{V_i - \min_j V_j}{\max_j V_j - \min_j V_j} \quad (9)$$

where the minimum and maximum are computed over the full set of units j . Higher values of `Idx_Vulnerab_Final` indicate higher (worse) vulnerability and potential deprivation.

III Results

A Spatial vulnerability dashboard

This section presents the spatial dashboard constructed through multi-dimensional indexing aforementioned at an unprecedented granular scale for CAR. The dashboard employs a standardized grid-cell approach with 5×5 km resolution, providing a replicable and scalable methodological framework that represents a significant advancement in spatial development analysis for fragile states in general and CAR in particular.¹⁶ This granular approach enables precise identification of vulnerability hotspots and might facilitate targeted policy interventions, while the standardized grid system ensures methodological consistency and comparability across different spatial units of analysis.

The dashboard comprises an overall vulnerability index and its six core vulnerability components that cover the dimensions aforementioned: local economic capacity, access to essential services (education, health, water), and exposure to flooding and conflict-related shocks. As also previously discussed, each index is normalized on a 0-100 scale, where higher values indicate better outcomes for capacity indicators (i.e., GDP and infrastructure components) and higher exposure for risk indicators. The spatial resolution adopted here provides critical advantages over traditional administrative-unit analyses, as it captures intra-regional heterogeneity and enables identification of localized vulnerability and potential deprivation patterns that would otherwise be obscured by administrative aggregation.

¹⁵As with flood risk exposure, higher values reflect more detrimental outcomes.

¹⁶The replication material is available [here](#).

Importantly, this methodological framework is fully adaptable to alternative spatial units of interest, from administrative boundaries to custom-defined zones, ensuring broad applicability across diverse analytical contexts. Section A.2 of the Appendix presents each dimension at the communal administrative (admin 3) level, showing which communes overperform or underperform relative to the national median of each component.

The composite vulnerability index reveals pronounced spatial heterogeneity in development challenges across the Central African Republic (Figure 4). Bangui and its surrounding areas appear relatively less vulnerable than the rest of the country, forming the only substantial region in the 0–24 range despite periodic exposure to lethal conflicts and flooding.¹⁷ Western remote regions—particularly areas around Berbérati, Bouar, and the southwestern prefectures—exhibit high composite vulnerability scores (75–100 range), indicated by the dark red shading. The concentration of elevated vulnerability in these western areas likely reflects the compound nature of development challenges in zones distant from the capital and simultaneously constrained by infrastructure deficits. The central corridor extending from Bangui through Bambari and Bouar displays intermediate (25–49) to high (50–74) vulnerability levels, shown in pale green and orange. Although these areas benefit from somewhat better economic connectivity and service infrastructure than the most vulnerable regions, persistent conflict exposure substantially heightens overall vulnerability. The spatial pattern suggests that proximity to major transport routes and urban centers provides only partial protection when conflict risks remain high. The northeastern and eastern regions exhibit more spatially dispersed vulnerability, with clusters of extreme vulnerability interspersed with largely uninhabited areas. Low population density in these zones creates distinct vulnerability dynamics, where the combination of remoteness, limited service infrastructure, and periodic exposure to lethal conflicts and climate hazards generates localized vulnerability hotspots.

Figures 5 through 8 present the spatial distribution of economic capacity and access to fundamental public services across CAR at the grid level. The total GDP index reveals a highly concentrated economic geography, with Bangui and its immediate periphery exhibiting the highest economic activity levels (index values exceeding 65), while vast rural areas display minimal economic activity (index values below 7.7).¹⁸ This stark spatial polarization underscores the capital-centric nature of the small economic activity in CAR,¹⁹ with secondary urban centers such as Bambari, Berbérati, and Bouar showing very modest economic activity clusters.

The education access landscape demonstrates greater spatial coverage than economic activity, with numerous areas achieving high primary education access scores (67–100 range), especially in the central part of the country and close to transportation corridors. By contrast, western remote areas and northeastern territories show more limited coverage. This pattern suggests that educational service provision has achieved broader geographic penetration than economic development, though significant gaps remain in peripheral areas.

Health care access presents a more constrained spatial distribution, with the majority of the territory falling within the lowest accessibility categories (0–29 range). Urban centers and their immediate surroundings demonstrate the highest health service accessibility, while extensive rural areas face severe health care access constraints. This spatial pattern indicates substantial geographic inequities in health care provision, with potential implications for population health outcomes, human capital development as well as social discontent stemming from likely relative deprivation.

Water access exhibits an intermediate spatial distribution pattern, with better coverage than health care but more limited than education. The distribution reveals clusters of high accessibility around major urban centers and along major transportation corridors, while remote areas, particularly in the eastern parts of CAR, show very limited water infrastructure access.

Figures 9 and 10 present the spatial distribution of environmental and conflict-related vulnerability exposures. The flooding exposure index reveals highly localized risk patterns, with elevated exposure concentrated along major river systems, particularly the Ubangi River corridor and its tributaries. Bangui faces particularly acute flood exposure given its riverside location, while cities such as Bambari, Berbérati, Birao, Bria, and Nola exhibit significant flood vulnerability. The concentrated nature of

¹⁷This assessment is relative to the national context, Bangui and surroundings remain highly deprived in comparison with international standards [World Bank, 2022, 2023].

¹⁸The split between primary GDP activities and secondary/tertiary activities is available in Section A.2 of the Appendix.

¹⁹Based on the state space model, the total GDP in CAR was around US\$1,890 million on average in 2021, when the EHCVM was finalized.

flood risk enables targeted flood management interventions in high-exposure areas.²⁰

Lethal conflict exposure over the years demonstrates a markedly different spatial pattern, with widespread distribution across the national territory and notable concentrations in strategically important locations. Major urban centers including Bambari, the capital city Bangui, Bangassou, and Bria, exhibit particularly high lethal conflict exposure indices, reflecting the complex interaction between population density, (political) rent capture, resource competition, and political instability. The extensive geographic spread of lethal conflict exposure underscores the pervasive nature of security challenges in CAR and the need for comprehensive conflict-sensitive development approaches.²¹

Figure 4: Overall vulnerability index at granular level

Overall vulnerability

Source: Authors' construction. *Notes:* Standardized grid-cell approach with 5×5 km resolution. The composite vulnerability index ranges from 0 to 100, with higher values indicating greater vulnerability (100 = most vulnerable; 0 = least vulnerable, relative to national standards). Gray areas on the map represent regions with no reported population. Red circles indicate Bangui and the ten subsequent major urban centers in CAR.

²⁰For instance, one primary objective of the World Bank's Provir project (started in 2023) is the management of flood and erosion risk protection in key urban centers, including Bangui and Berbérati. For further information, see the official press release from the World Bank, available [here](#).

²¹For instance, the World Bank's Local Governance and Community Resilience Project (started in 2023). For further information, see the project appraisal document, available [here](#).

Figure 5: GDP index

Source: Authors' construction. *Notes:* Standardized grid-cell approach with 5×5 km resolution. The year 2021 is used as the reference year to ensure consistency with the EHCVM survey data. Economic activity concentration measured through relevant remote sensing and geocoded data. Index ranges from 0 (minimal economic activity) to 100 (maximum economic density). Red circles indicate Bangui and the ten subsequent major urban centers in CAR. Intervals are computed using Fisher grouping method.

Figure 6: Education access index

Source: Authors' construction. *Notes:* Standardized grid-cell approach with 5×5 km resolution. Spatial accessibility to all primary education facilities based on travel time and infrastructure density. Higher values indicate better educational access. Gray areas on the map represent regions with no reported population. Red circles indicate Bangui and the ten subsequent major urban centers in CAR. Intervals are computed using Fisher grouping method.

Figure 7: Health access index

Source: Authors' construction. *Notes:* Standardized grid-cell approach with 5×5 km resolution. Proximity and accessibility to any health facilities. Index reflects travel time and service availability, with higher values indicating better health care access. Gray areas on the map represent regions with no reported population. Red circles indicate Bangui and the ten subsequent major urban centers in CAR. Intervals are computed using Fisher grouping method.

Figure 8: Water access index

Source: Authors' construction. *Notes:* Standardized grid-cell approach with 5×5 km resolution. Spatial distribution of water point accessibility and infrastructure coverage. Higher values represent better water access conditions. Gray areas on the map represent regions with no reported population. Red circles indicate Bangui and the ten subsequent major urban centers in CAR. Intervals are computed using Fisher grouping method.

Figure 9: Floods index

Source: Authors' construction. *Notes:* Standardized grid-cell approach with 5×5 km resolution. Spatial vulnerability to flood events based on topographical, hydrological, and historical flood data. Higher values indicate greater flood exposure risk. Gray areas on the map represent regions with no reported population. Red circles indicate Bangui and the ten subsequent major urban centers in CAR. Intervals are computed using Fisher grouping method.

Figure 10: Conflict index

Source: Authors' construction. *Notes:* Standardized grid-cell approach with 5×5 km resolution. The period 2016-21 (rolling average) is used as a reference to ensure consistency with the EHCVM survey data. Spatial distribution of conflict risk based on historical incident data and proximity to lethal conflict zones. Higher values represent greater lethal conflict exposure, with notable concentrations in urban centers and strategic locations. Gray areas on the map represent regions with no reported population. Red circles indicate Bangui and the ten subsequent major urban centers in CAR. Intervals are computed using Fisher grouping method.

B Cross-validation with household survey data

1 Empirical strategy

To validate the spatial vulnerability indices developed in this analysis, cross-validation is employed using household-level data from the EHCVM 2021. Household wealth indices are constructed following the standardized Demographic and Health Surveys (DHS) methodology.²² Households are then spatially matched to their corresponding 5×5 kilometer grid cells to examine the relationship between the spatial indices and household-level welfare outcomes. The empirical specification takes the following form:

$$W_{i,g} = \alpha + \beta_1 GDP_g + \beta_2 Education_g + \beta_3 Health_g + \beta_4 Water_g + \gamma X_{i,g} + \delta_r + \epsilon_{i,g} \quad (10)$$

where $W_{i,g}$ represents the wealth index for household i located in grid cell g , GDP_g denotes the economic activity index for grid cell g , which can alternatively be decomposed into primary activities and secondary/tertiary activities, and $Education_g$, $Health_g$, and $Water_g$ represent the respective service access indices. The vector $X_{i,g}$ captures household-level control variables,²³ δ_r represents regional or prefectural fixed effects, and $\epsilon_{i,g}$ is the error term. When explicitly indicated, standard

²²For further information, see the official documentation from the DHS available [here](#).

²³The selection of household-level controls $X_{i,g}$ is derived from the World Bank's Poverty Assessment [World Bank, 2023]. It includes demographic characteristics (i.e., household size, age and gender of household head), human capital variables (i.e., educational attainment of household head), employment sector indicators (i.e., sectoral activity of household head), and displacement status (i.e., IDPs in ordinary households or in refugee camps).

errors are clustered at the prefectural level to account for spatial correlation. The high spatial resolution of our indices enables identification from within-administrative variation in local conditions.

For shock exposure analysis, the following slightly alternative specification is estimated:

$$W_{i,g} = \alpha + \beta_1 GDP_g + \beta_2 Floods_g + \beta_3 Conflicts_g + \gamma X_{i,g} + \delta_r + \epsilon_{i,g} \quad (11)$$

where $Floods_g$ and $Conflicts_g$ represent exposure indices for environmental and conflict-related risks respectively.²⁴

2 Validation results for economic capacity and service access

Table 1 presents the validation results for economic capacity and basic service access indices. The findings provide strong empirical support for the spatial vulnerability framework developed in this study. The GDP index demonstrates a robust positive and statistically significant association with household wealth across all specifications. This relationship remains statistically significant at the 1 or 0.1 percent level even after controlling for regional and prefectural fixed effects, confirming that areas with higher local economic activity as measured through relevant remote sensing and geocoded data effectively correspond to higher household welfare levels.

All three service access indices display consistently positive and significant associations with household wealth, confirming their relevance as welfare predictors. Health access, in particular, achieves its strongest significance under the most demanding specification with prefectural fixed effects (Column 3), indicating that proximity to health facilities captures meaningful within-prefecture variation in welfare outcomes beyond what broader administrative characteristics explain. The robustness of these results across alternative fixed-effects specifications further strengthens the credibility of the spatial indices. In particular, the inclusion of prefectural fixed effects with clustered standard errors (Column 3) accounts for unobserved heterogeneity at a key administrative level. Although this specification attenuates the magnitude of some coefficients, their statistical significance persists, indicating that the indices capture genuinely local variation in welfare-relevant conditions.²⁵

Tables A.2 and A.3 in the Section A.3 of the Appendix report results with GDP disaggregated by sector. Primary-sector GDP maintains a robust positive and significant association with household wealth across all specifications, including under prefectural fixed effects. The secondary and tertiary sectors, by contrast, lose significance once fixed effects are introduced. This pattern likely reflects the spatial concentration of secondary and tertiary activities in a few areas—chiefly Bangui—whereas primary activities, particularly subsistence agriculture, are more widely distributed across the country [World Bank, 2022].

²⁴Both GDP_g and $Conflicts_g$ have panel dimensions but are reported with respectively 2021 and 2016-21 (rolling average) as reference years to ensure consistency with the EHCVM survey data.

²⁵As of 2025, in both legal frameworks and practical applications, prefectures continue to hold greater relevance and authority than communes in the exercise of routine state functions, security measures, and inter-ministerial coordination beyond Bangui. The operational capacities of communes are markedly limited by insufficient decentralization and a severe lack of resources [World Bank, 2025].

Table 1: Spatial vulnerability indices and household wealth: Basic Services and economic activity

	Households' baseline wealth index		
	Col.1	Col.2	Col.3
GDP	0.106*** (0.006)	0.050** (0.009)	0.050*** (0.009)

Fixed effects	No	Regional	Prefectoral
Clustered standard errors	No	Yes	Yes

* p < 0.05, ** p < 0.01, *** p < 0.001

Source: Authors' construction. *Notes:* Dependent variable is the household wealth index constructed following DHS methodology using EHCVM 2021 data. All spatial indices are measured at 5×5 km grid cell level and normalized on 0-100 scale. The GDP index is constructed using relevant remote sensing and geocoded data. Service access indices are derived from travel time to facilities and the density of associated infrastructure. Higher values mean higher local economic activities or better service access. Additional covariates—household (HH) size; presence of IDPs in ordinary households or camps; whether the HH head is a woman; HH head's education level (primary, secondary first cycle, secondary second cycle, or higher); age of the HH head; and HH employment status (secondary sector, tertiary sector, or inactive/unemployed)—are included as controls but omitted from the table for brevity. Regional fixed effects account for the seven administrative regions of CAR, and prefectural fixed effects control for the 20 prefectures. Standard errors are clustered at the regional level in Column (2) and the prefectural level in Column (3). The sample comprises 6,264 households spatially matched to grid cells.

3 Shock exposure validation

Table 2 examines the relationship between spatial vulnerability indices and household wealth in the context of environmental and conflict-related exposures. The lethal conflict exposure index exhibits a positive and statistically significant association with household wealth, a finding that initially appears counterintuitive but reflects important conflict dynamics in fragile states. The coefficient indicates that areas with higher conflict exposure paradoxically correspond to higher household wealth levels.

This seemingly paradoxical relationship likely reflects the strategic targeting behavior of armed groups against the state, its allies and proxies over the past decade, who concentrate activities in economically valuable areas including urban centers, mining regions, and areas with valuable natural resources or infrastructure [Buhaug and Rød, 2006, Berman et al., 2017]. Rather than indicating that conflict improves welfare, this relationship plausibly demonstrates that (relative) wealth concentration creates attractive targets for armed groups, generating the positive spatial correlation between lethal conflict exposure and economic activity. This finding underscores the complex relationship between economic development and security in fragile states [Laville and Mandon, 2025], where even relative prosperity may increase rather than decrease exposure to conflict risks. By contrast, the flooding exposure index shows no statistically significant association with household wealth.

Table 2: Spatial vulnerability indices and household wealth: Shock exposure and economic activity

	Households' wealth index		
	Col.1	Col.2	Col.3
GDP	0.095*** (0.007)	0.048** (0.010)	0.047*** (0.010)

Fixed effects	No	Regional	Prefectoral
Clustered standard errors	No	Yes	Yes

* p < 0.05, ** p < 0.01, *** p < 0.001

Source: Authors' construction. *Notes:* Dependent variable is the household wealth index constructed following DHS methodology using EHCVM 2021 data. All spatial indices are measured at 5×5 km grid cell level and normalized on 0-100 scale. The GDP index is constructed from remote sensing and geocoded data. The risk indices measure physical exposure to flooding and lethal conflict, incorporating travel time to (potential) events. Higher values mean higher local economic activities or better service access. Additional covariates—HH size; presence of IDPs in ordinary households or camps; whether the HH head is a woman; HH head's education level (primary, secondary first cycle, secondary second cycle, or higher); age of the HH head; and HH employment status (secondary sector, tertiary sector, or inactive/unemployed)—are included as controls but omitted from the table for brevity. Regional fixed effects account for the seven administrative regions of CAR, and prefectural fixed effects control for the 20 prefectures. Standard errors are clustered at the regional level in Column (2) and the prefectural level in Column (3). The sample comprises 6,264 households spatially matched to grid cells.

4 Robustness checks on wealth measurement

Tables A.4 and A.5 in Section A.3 of the Appendix report an alternative computation of the wealth index following the DHS methodology. This approach applies distinct procedures for urban and rural households²⁶ and confirms the robustness of the baseline results in both magnitude and statistical significance.

IV Discussion

The multidimensional vulnerability assessment integrates a Bayesian state-space model, friction-based accessibility metrics, and remote sensing and geocoded data, revealing stark spatial inequalities across CAR. Economic activity concentrates heavily in Bangui, while vast rural areas exhibit minimal economic presence. Service access varies markedly: education achieves relatively broad geographic coverage, particularly in the better-connected central regions; health care access remains severely constrained across most of the territory; and water access shows intermediate coverage concentrated around urban centers and main transportation corridors.

Risk exposure analysis uncovers distinct spatial patterns for different hazards. Flooding exposure concentrates along major river systems, particularly affecting Bangui and cities such as Bambari, Berbérati, Birao, Bria, and Nola. Lethal conflict exposure demonstrates widespread distribution across the national territory with notable concentrations in strategically important urban centers including Bambari, Bangui, Bangassou, and Bria.

The cross-validation exercise provides strong empirical support for the indices derived from the state space model, as well as relevant remote sensing and geocoded data. Local economic activity estimates and all service access measures—education, health, and water—exhibit consistently positive and significant relationships with household wealth. Health access, in particular, achieves its strongest association under prefectural fixed effects, suggesting that the index captures genuinely local variation in welfare-relevant conditions. Primary-sector GDP remains positively associated with household wealth, whereas the secondary and tertiary sectors lose significance once fixed effects are applied, consistent with their urban concentration, mostly in Bangui, and the widespread nature of primary

²⁶As for the baseline wealth index, see the official documentation from the DHS available [here](#).

activities. Moreover, the analysis reveals a counterintuitive positive correlation between lethal conflict exposure and household wealth, reflecting strategic targeting of economically valuable areas by armed groups rather than protective effects of prosperity [Buhaug and Rød, 2006, Berman et al., 2017]. Regarding flooding, the data indicate that flood exposure correlates with wealth primarily through administrative-level factors (e.g., Bangui’s effect) rather than localized, fine-grained variations.

These findings have immediate policy implications for CAR and broader applicability to other fragile states. The extreme spatial polarization underscores the need for spatially differentiated development strategies that address both the concentration of economic activity and the multidimensional nature of vulnerability. The positive conflict-wealth correlation necessitates conflict-sensitive approaches to development programming that account for the security risks associated with economic activity.

The framework developed here offers a scalable template for alternative data applications across sub-Saharan Africa and other regions where conventional statistical systems face severe capacity constraints. Analogous frameworks are currently being developed for Afghanistan and Gabon by the World Bank, and viable alternatives exist when geocoded infrastructure data are not directly accessible (e.g., integrating OpenStreetMap data with machine learning approaches). By bridging satellite-derived insights and ground-truth welfare outcomes, this research contributes to the growing toolkit for monitoring progress toward sustainable development goals in the world’s most vulnerable populations.

Appendix

A.1 Sources for relevant remote sensing and geocoded data

1 Economic activity measurement

The analysis employs Defense Meteorological Satellite Program (DMSP) satellite data for long-term modeling combined with extended DMSP datasets through 2022 from the Earth Observation Group at Colorado School of Mines. Visible Infrared Imaging Radiometer Suite (VIIRS) data, while superior for rural area detection, remains unavailable before 2013 and therefore cannot support the full temporal scope required.

The analysis also incorporates complementary remote sensing indicators including population density, built-up area coverage, and infrastructure survey data from ICASEES to capture secondary and tertiary sector activities that operate without consistent electricity access.

Land cover classification data enables identification of primary economic activities through cropland delineation combined with Normalized Difference Vegetation Index (NDVI) measurements as agricultural productivity proxies. Forestry sector activities are captured through forest density indicators combined with deforestation indices to identify active logging areas. Mining sector activities utilize known industrial and artisanal mine locations for spatial allocation.

2 Service accessibility data

Physical accessibility to essential public services relies on comprehensive facility location databases. Health center locations, primary education schools, and water point coordinates are sourced from ICASEES. These datasets enable travel time calculations and accessibility modeling for service provision analysis.

3 Risk exposure data

Conflict exposure measurement utilizes ACLED records, which provide georeferenced violent event data with temporal precision. This enables spatial proximity calculations and conflict density mapping for vulnerability assessment. This paper focuses on lethal conflicts only. Flood hazard exposure employs Fathom Global 3.0 datasets, which provide comprehensive flood risk modeling incorporating topographical vulnerability and historical flood occurrence patterns. These data support identification of areas with elevated environmental risk exposure.

The comprehensive data sources and their respective spatial and temporal resolutions are detailed in Table A.1.

Table A.1: Relevant remote sensing and geocoded data sources

Variable	Resolution	Temporality	Source(s)
NTLs, DMSP	1000 m	1992-2022	EOG, Colorado School of Mines
NTLs, VIIRS	500 m	2013-22	EOG, Colorado School of Mines

A.3 Robustness checks on survey validation

Tables A.2 and A.3 examine the robustness of the baseline results to disaggregation of GDP by economic sector. The primary sector GDP index demonstrates robust positive associations with household wealth across all specifications, maintaining statistical significance at conventional levels even under the most demanding prefectural fixed effects specification. In contrast, the secondary and tertiary sectors GDP index, while positive and significant in the basic specification, loses statistical significance once regional or prefectural fixed effects are introduced. This differential pattern likely reflects the distinct spatial distributions of economic activities across CAR's territory. Secondary and tertiary sector activities concentrate predominantly in Bangui and a limited number of urban centers, generating strong spatial correlation with administrative boundaries, which is likely absorbed by fixed effects. Primary sector activities, particularly subsistence agriculture, exhibit broader geographic distribution across rural areas, providing variation within administrative units that enables identification even with fixed effects controls. The health access index similarly strengthens under prefectural fixed effects, achieving its highest significance level in this specification, consistent with the baseline results.

Table A.2: Spatial vulnerability indices and household wealth: Basic services and economic activity disaggregated

Source: Authors' construction. *Notes:* Dependent variable is the household wealth index constructed following DHS methodology using EHCVM 2021 data. All spatial indices are measured at 5×5 km grid cell level and normalized on 0-100 scale. Indices for primary and secondary/tertiary GDP are constructed using remote sensing and geocoded data. The risk indices measure physical exposure to flooding and lethal conflict, incorporating travel time to (potential) events. Higher values mean higher local economic activities or better service access. Additional covariates—HH size; presence of IDPs in ordinary households or camps; whether the HH head is a woman; HH head's education level (primary, secondary first cycle, secondary second cycle, or higher); age of the HH head; and HH employment status (secondary sector, tertiary sector, or inactive/unemployed)—are included as controls but omitted from the table for brevity. Regional fixed effects account for the seven administrative regions of CAR, and prefectoral fixed effects control for the 20 prefectures. Standard errors are clustered at the regional level in Column (2) and the prefectoral level in Column (3). The sample comprises 6,264 households spatially matched to grid cells.

Tables A.4 and A.5 assess robustness to alternative wealth index construction methodologies. Following DHS guidelines, this alternative specification employs distinct asset weighting procedures for urban and rural households to account for differential asset importance across spatial contexts. The complex wealth index construction recognizes that certain assets may serve different functions or carry different economic values in urban versus rural settings, necessitating context-specific weighting schemes. The validation results using this alternative wealth measure closely mirror the baseline findings. The GDP index remains strongly significant across all specifications, and the health access index maintains significance at the 0.1 percent level throughout, reinforcing the robustness of the infrastructure indices. The conflict exposure index similarly preserves its positive and significant association with household wealth. The stability of findings across alternative wealth measurement approaches strengthens confidence in the spatial vulnerability indices' validity and suggests that the observed relationships reflect genuine associations between spatial conditions and household welfare rather than artifacts of particular measurement conventions.

Table A.4: Spatial vulnerability indices and household wealth: Basic Services and economic activity (Complex wealth measurement)

	Households' complex wealth index		
	Col.1	Col.2	Col.3
GDP	0.115*** (0.006)	0.055*** (0.010)	0.055*** (0.010)
Access to health index	0.006*** (0.001)	0.005*** (0.001)	0.007*** (0.001)
Access to primary education index	0.005*** (0.001)	0.004*** (0.001)	0.003* (0.001)
Access to water index	0.004*** (0.001)	0.003** (0.001)	0.003* (0.001)

Source: Authors' construction. *Notes:* Dependent variable is the household wealth index constructed following DHS methodology using EHCVM 2021 data. All spatial indices are measured at 5×5 km grid cell level and normalized on 0-100 scale. The GDP index is constructed using relevant remote sensing and geocoded data. Service access indices are derived from travel time to facilities and the density of associated infrastructure. Higher values mean higher local economic activities or better service access. Additional covariates—HH size; presence of IDPs in ordinary households or camps; whether the HH head is a woman; HH head's education level (primary, secondary first cycle, secondary second cycle, or higher); age of the HH head; and HH employment status (secondary sector, tertiary sector, or inactive/unemployed)—are included as controls but omitted from the table for brevity.
